CMPE 415
Verilog Case-Statement Based State Machines II
Prof. Ryan Robucci
A very common framework being described and implemented is a Finite State Machine with a Datapath: a data path controlled by signals from a FSM.
Control and Datapath Partitioning

• Datapath operations can be encoded in the state machine description or can be built separately.
  • If pre-built modules are used, as is common, the datapath is necessarily a separate description.
  • Often the datapath represents the algorithm calculations, separating the datapath code makes the code more readable.
  • Coding datapath separately can allow more explicit influence over and insight into the resources used for computation while separating details of control code.
  • Can sometimes think of datapath as implementing instructions for the controller to invoke/call.
  • Separating the datapath code can allow better reuse under a different scheduling of operations (implementing a different algorithm).
• In general, designing the datapath first and then the control is a good strategy.
## Controller FSM vs Datapath

</tbody>
</table>
Divide and Conquer

- Datapath operations can be encoded in the state machine description or can be built separately.

- First consider partitioning. Identify elements in the datapath from experience with traditional digital systems (e.g. communications modules, arithmetic modules, multiplexor's and demultiplexors, registers and multi-word buffers, FIFOs, IP Cores etc...). Identify the control signals required and the status/condition information required to make decisions on the control.
• Characterized by:
  • A set of states
  • A set of inputs and outputs
  • A state transition function
  • An output function
• Hardware Implementation:
  • Current State held in a register
  • Any additional status information held in status registers
  • Next-State and State Control Logic Determines next state and control signals based on registers
  • Datapath implements operations on data under control of state control logic
How to add pauses?

Some Options:

– Add “top” level wait states to state machine in each place needed
  - Create a single embedded wait state to jump to and return to from multiple states using a “return” register (embedded states)
  - Use a counter
    a) Use external counter or implement one with another state machine and interface to it
    b) embed something like a counter in the coding of the state machine creating substates using the counter as an extended state register.

Thought Question

• Better to grow state register or use a separate counter variable?
Question: Consider if master is slow, and go is left high too long.

To alter the behavior, can use
always @ (posedge clk) go_prev<=go;
to save previous value and use
(start==1 && start_prev==0)
as a condition

Alternatively, what if we want the system to cycle again immediately without startA going low if start is left high?
• FSM typically lack any hierarchy. There is no way to connect details of state-machines leading to state explosion. Otherwise, a hierarchy of states is quite useful for organizing an algorithm.
• Consider two state machines. Maybe one captures user input like desired temperature, it has states, inputs and outputs appropriate to perform that task. Perhaps the other controls a heating element based on measured and desired temperature. Separated, they may be fairly simple, but what happens when they are described as a single, flat state machine? A multiplicative effect. Two three-state FSMs became one nine-state FSM.

• This motivates partitioning into multiple state machines in hardware design.
Global Exceptions

• Now, see what happens if a single new condition, a universal exception must be added.
• A dramatic result from only one new condition. Readability and perhaps feasibility of mentally managing the FSM is severely impacted.
Meanwhile in software...

• A single if statement can be added, taking advantage of the hierarchy of logic embedded in code.

```java
if (exception) {
    do this
} else {

switch (current_state) {
    case A: ...
    case B: ...
    case C: ...
    case D: ...
}
```

```java
switch (current_state) {
    case A: ...
    case B: 
    case C: 
    case D: 
```
• Think about the delay examples given earlier using a counter. The counter was implementing one form of hierarchical states.
• Consider waiting for an acknowledgment signal for $2^{20}$ clock cycles. This would require $\sim 1$ Million states with the condition to move to the next state or proceed to end state if acknowledge was received.
In the following slides, we will consider examples of computational FSMs. These are used to describe and synthesize multi-cycle computations. The number of state transitions defined are typically less than with a complex controller FSM. A more regular forward orderly progression through the states is typical, and the designer’s thought processes may be focused on the computation being performed in each state and the resulting partial results (in registers), as opposed to the output during the state. Thus, it becomes more reasonable to use a single edge-triggered always block in the design. The fewer number of transition decisions (branches) makes the concern of code bloat negligible.
As we are designing Multi-Cycle computations, we may consider two optimizations:

Rescheduling – moving internal operations to other states

Resource sharing – utilizing same component in multiple states
module FSM_opt(
    output reg [7:0] f,
    input clk,
    input wire [7:0] i,
    input wire [7:0] j,
    input wire [7:0] k,
    input rst
);

reg [7:0] CS;
reg [7:0] i_int,j_int,k_int;

parameter S_0 = 8'b00000000;
parameter S_1 = 8'b00000001;
parameter S_2 = 8'b00000010;
always @ (posedge clk) begin
  if (rst) begin
    CS<=S_0;
    f<=0;
  end else begin
    case (CS)
      S_0: begin
        i_int<=i;
        j_int<=j;
        k_int<=k;
        CS<=S_1;   end
      S_1: begin
        CS<=S_2;   end
      S_2: begin
        m=i_int*j_int;
        f<=m*k_int;
        CS<=S_0;   end
    endcase
  end
endmodule

Multi-cycle computation:
Note, the single-block style here was used since the state transition sequence is straightforward. Also, the data path is combined with the controller.
We are not worried about “code bloat” from having to code each output on every transition.
Instead of concentrating on **timing coincidence** of state and outputs vs **coding coincidence** of state and outputs, we are focused on the coincidence of states and computations. In this single block style the computation performed and resources required for each are clear, though the corresponding output of each computation is seen and can be used on the cycle following the corresponding state indicated in the state register.
RTL suggested from Code

Only data flow connections shown
Alternative RTL with faster operation
always @ (posedge clk) begin
    if (rst) begin
        CS<=S_0;
        f<=0;
    end else begin
        case(CS)
            S_0: begin
                i_int<=i; j_int<=j; k_int<=k;
                CS<=S_1;
            end
            S_1: begin
                m<=i_int*j_int;
                CS<=S_2;
            end
            S_2: begin
                //m=i_int*j_int;
                f<=m*k_int;
                CS<=S_0;
            end
        endcase
    end
end
endmodule

Rescheduling this multiply allows for faster clock speeds (we assume two clock cycles were required at the system level). Some synthesizers may do similar types of rescheduling for you.
module FSM_opt(
    output reg [7:0] f,
    output reg [7:0] g,
    input  clk,
    input wire [7:0] i,
    input wire [7:0] j,
    input wire [7:0] k,
    input  rst
);

reg [7:0] CS;
reg [7:0] i_int, j_int, k_int;

parameter S_0 = 8'b00000000;
parameter S_1 = 8'b00000001;
parameter S_2 = 8'b00000010;
always @ (posedge clk) begin
    if (rst) begin
        CS<=S_0;
        f<=0;
        h<=0;
    end else begin
        case (CS)
            S_0: begin
                i_int<=i; j_int<=j; k_int<=k;
                CS<=S_1; end
            S_1: begin
                CS<=S_2; end
            S_2: begin
                f<=i_int*j_int; h<=j_int*k_int;
                CS<=S_0; end
        endcase
    end
endmodule
Suggested RTL

FSM Controller
Alternative RTL with lower gate count
```verilog
always @(posedge clk) begin
    if (rst) begin
        CS<=S_0;
f<=0;
g<=0;
end else begin
    case(CS)
        S_0: begin
            i_int<=i; j_int<=j; k_int<=k;
            CS<=S_1; end
        S_1: begin
            f_int<=i_int*j_int;
            CS<=S_2; end
        S_2: begin
            g<=k_int*j_int; f<=f_int;
            CS<=S_0; end
    endcase
e ndcase
end
endmodule
```

Explicitly coding the rescheduling is simple enough, but explicitly coding the resource sharing isn't.
... 

always @ (posedge clk) 

...

case (CS) 
S_0:begin q<=r+s; CS<=S_1; end 
S_1:begin CS<=S_2; end 
S_2:begin qout<=q+5; CS<=S_0; end 
...

...

always @ (posedge clk) 

...

case (CS) 
S_0:begin q<=r+s; CS<=S_1; end 
S_1:begin q<=q+5; CS<=S_2; end 
S_2:begin qout<=q; CS<=S_0; end 
...

Another Rescheduling Example

\begin{verbatim}
input [7:0] i,j,k;
output [7:0] f,h;
reg [7:0] f,g,h,q,r,s;
always @ (posedge clk)
...
    case (CS)
      S_0:begin f<=i+j; g<=j*23;   CS<=S_1; end
      S_1:begin h<=f+k;            CS<=S_2; end
      S_2:begin f<=f*g; q<=r*s;    CS<=S_0; end
...

Externally Equivalent Alternative:

S_0:begin f<=i+j; g<=j*23;   CS<=S_1; end
S_1:begin h<=f+k; q_int<=r*s; CS<=S_2; end
S_2:begin f<=f*g; q<=q_int;  CS<=S_0; end

Externally Equivalent Alternative:

S_0:begin f<=i+j; g<=j*23;   CS<=S_1; end
S_1:begin h<=f+k; g<=f*g;   CS<=S_2; end
S_2:begin f<=g; q<=r*s;     CS<=S_0; end
\end{verbatim}

FSM Synthesizers can automatically try these variations:

Movement of \( q=r*s \) using a temporary variable

Movement of \( f*g \)
The state encoding effects the size of the decoder, speed, dependent logic optimization, etc.

Enencodings supported by Xilinx:

- Auto
- One-Hot
- Gray
- Compact
- Johnson
- Sequential
- User
- Speed 1
- RAM-based

State Encoding

- **Auto**: In this mode, XST tries to select the best suited encoding algorithm for each FSM.
- **One-Hot**: One-hot encoding is the default encoding scheme. Its principle is to associate one code bit and also one flip-flop to each state. At a given clock cycle during operation, one and only one bit of the state variable is asserted. Only two bits toggle during a transition between two states. One-hot encoding is very appropriate with most FPGA targets where a large number of flip-flops are available. It is also a good alternative when trying to optimize speed or to reduce power dissipation.
State Encoding

• Gray: Gray encoding guarantees that only one bit switches between two consecutive states. It is appropriate for controllers exhibiting long paths without branching. In addition, this coding technique minimizes hazards and glitches. Very good results can be obtained when implementing the state register with T flip-flops.

• Compact: Compact encoding consists of minimizing the number of bits in the state variables and flip-flops. This technique is based on hypercube immersion. Compact encoding is appropriate when trying to optimize area.
State Encoding

• Johnson: Like Gray, Johnson encoding shows benefits with state machines containing long paths with no branching.
• Sequential: Sequential encoding consists of identifying long paths and applying successive radix two codes to the states on these paths. Next state equations are minimized.
State Encoding

• Speed1: Speed1 encoding is oriented for speed optimization. The number of bits for a state register depends on the particular FSM, but generally it is greater than the number of FSM states.
• User: In this mode, XST uses original encoding, specified in the HDL file. For example, if you use enumerated types for a state register, then in addition you can use the ENUM_ENCODING constraint to assign a specific binary value to each state. Please refer to "Design Constraints" chapter for more details.
• RAM-Based Finite State Machine (FSM) Synthesis: Large Finite State Machine (FSM) components can be made more compact and faster by implementing them in the block RAM resources provided in Virtex® devices and later technologies. FSM Style (FSM_STYLE) directs XST to use block RAM resources for FSMs.
XST can add logic to your Finite State Machine (FSM) implementation that will let your state machine recover from an invalid state. If during its execution, a state machine enters an invalid state, the logic added by XST will bring it back to a known state, called a recovery state. This is known as Safe Implementation mode.

By default, XST automatically selects a reset state as the recovery state.
• One-hot coding is good for speed and simplicity of state decoding logic and state incrementing.
• More compact codes such as standard binary encoding generally require a smaller state register than one-hot coding at the possible cost of size and speed. But this depends on the density of comb. logic vs. registers the supporting HW platform and in the design. FPGAs have many registers and so the cost of additional combinatorial logic may large compared to the savings from needing less registers.
• Codes where only one or two bits change at a time in the state register may be beneficial. Less transitions may lead to less power depending on overall design. Can minimize the chance of metastability errors (such as systems with tight timing, or radiation vulnerability). These codes may also minimize logic glitches.
The XST log file reports the full information of recognized Finite State Machine (FSM) components during the Macro Recognition step. Moreover, if you allow XST to choose the best encoding algorithm for your FSMs, it reports the one it chose for each FSM. As soon as encoding is selected, XST reports the original and final FSM encoding. If the target is an FPGA device, XST reports this encoding at the HDL Synthesis step. If the target is a CPLD device, then XST reports this encoding at the Low Level Optimization step.

Constraints/Compiler Directives

• Most synthesizers support various instructions to modify synthesis behavior
  • http://www.xilinx.com/itp/xilinx8/books/data/docs/xst/xst0064_8.html#wp255324
• Many options can be applied globally or on a per module instance or even per block level.
• Some are entered in constraint files, as a command-line option or inline via special commented tags:

```vhdl
  casex select // synthesis full_case
  4'b1xxx: res = data1;
  4'bx1xx: res = data2;
  4'bxx1x: res = data3;
  4'bxxx1: res = data4;
```

  - **enum_encoding**
    - sets encoding when fsm_extract is used to select user
A word on default case

• You should not automatically add default case to synthesize a FSM since the logic has to cover many unnecessary states
  • Check documentation for your synthesizer's behavior
• Special effort may be required to have the synthesizer ignore the default case yet allow logging in simulation:

    // synopsys translate_off
default: $display(“He’s dead, Jim.”);  // synopsys translate_on
A word on states, the state register, and registers for variables serving as extended state variables

• In-class example given
• Technically, every register in a digital system is a part of the state. What variables you decide to think of as state in your state diagram and what is coded in the CS register and used in the case statement is up to you.
• When there are many similar states, sometimes combining them in code and adding a register for a variable makes sense. This can reduce the state decoding and state logic and may make the code more maintainable and easier to read.
Additional Synthesis Options and Directives
